ABSTRACT

Introduction: Indonesia is a country with a large agricultural and industry, known to utilize various types of pesticides, as well as several other industries with uncontrolled pollution levels distributed across the nation. Besides, numerous studies have stated the adverse effects of chemicals substances used in daily life and industrial waste on the health of living things, including humans. This study aimed to determine the infertility characteristic in the agricultural and industrial areas in Karawang Regency, West Java Province, Indonesia.

Methods: The study was conducted retrospectively on medical records. Therefore, this study determined the infertility characteristics based on sperm analysis, the etiology of the causes of infertility in female, and the diagnosis of infertility. Data collection was obtained from patients’ medical records in the Infertile Poly of Mitra Bunda Amanda Hospital Karawang, Karawang Regency, West Java Province, Indonesia.

Result: The results showed infertility was most prevalent in males aged 30-40 years (55.79%) and females below 30 years (61.05%). Furthermore, the male and female’s most prevalent educational qualification (33.68% and 36.84%, respectively) was discovered to be high school diploma. In terms of occupation, most male (56.84%) were laborers, while the female was mostly housewives (36.84%). In addition, the male and female’s most prevalent educational qualification (33.68% and 36.84%, respectively) were high school diploma. Furthermore, the male and female’s most prevalent educational qualification (33.68% and 36.84%, respectively) were high school diploma. In terms of occupation, most male (56.84%) were laborers, while the female was mostly housewives (36.84%).

Conclusion: Primary infertility of male and female factors, polycystic ovary syndrome and oligoasthenoteratozoospermia dominate the infertile population in agricultural and industrial areas in Karawang Regency, West Java Province, Indonesia.

Keywords: pollutants, sperm analysis, infertility, oligoasthenoteratozoospermia, polycystic ovary syndrome.

INTRODUCTION

Pollutants are harmful to human health and damage the environment. Pollutants in the human environment have various effects that are detrimental to health to cause disease.1 The character of disease risk due to exposure to multi-pollutants can be determined using an “environmental risk score”.2 Environmental pollutants with estrogeneric effects generally have biological effects in women, as pollutants with anti-androgenic effects that affect male fertility.3 Pollutants from agricultural and industrial activities can pollute the air, water and soil. Of course, pollutants can move places. Pollutants in the air can move to water and land or vice versa. Directly or indirectly, pollutants can cause human health problems. Air pollution can occur because it contains particles with aerodynamic diameters below 10 and 2.5 µm (PM10 and PM2.5). Apart from that, it can also contain NO, NO2, NOx and SO2. It has been proven that air pollutants cause endocrine disorders and hormonal disturbances. Women exposed to high concentrations of air pollutants, namely PM 2.5, NO, NO2, NOx and SO2, have a high risk of developing polycystic
downstream is caused by excess waste from domestic, agricultural and industrial activities. It has been shown that air pollution plays a role in infertility. Factory waste is a disruptive endocrine hormone able to damage the body’s endocrine system through various mechanisms. Moreover, that pollutants disrupt spermatogenesis, leading to decreased reproductive capacity in exposed populations. The results of previous studies show the effect of environmental lead pollution on blood lead and sex hormone levels in the electronic waste disposal area. Previous studies have also shown that pollution affects chromosomes, thereby affecting infertility and sex hormone levels. Infertility is still a problem for many married couples. It was also stated that the average age of childbearing in women was increasing. Moreover that infertility in Indonesia occurs in about 10-15% of couples of childbearing age. Based on the researchers’ data, it is necessary to conduct a study on the

ovary syndrome. Besides that, it has been shown that particles less than 0.3 μm in diameter can dominate the acute effects of particulate air pollution resulting in cardiac autonomic dysfunction. Furthermore, it was reported that PM interferes with energy metabolism, thereby disrupting the endocrine glands and becoming a risk for cardiovascular disease. In this regard, we have reported a case of aortic enlargement on the cadaveric heart and great vessel dimensions. Because that, studies are still needed on the effect of pollutants on aortic enlargement. That is important because cardiovascular disease as a risk factor has been shown to have a strong correlation with a history of infertility in women of childbearing age and menopause. Moreover, chemicals used in the textile industry are believed to produce persistent organic pollutants (POPs). These chemicals include dichlorodiphenyltrichloroethane (DDT), dichlorodiphenylchloroethylene (p,p’-DDE) and polychlorinated biphenyls (PCBs). POP is a stable lipophilic compound found in the environment. These pollutants are difficult to break down, insoluble in water, and accumulate in the human body. Furthermore, pollutants in the body can cause human health problems. How are people living in agricultural and industrial areas exposed to pollutants?

Of course, people living in the area are exposed to various pollutants from agricultural and industrial activities. One proof that agricultural and industrial activities in Karawang Regency, West Java Province, Indonesia, impact the environment can be seen in the water quality of the Citarum river. The Citarum River is a large and long river in West Java that crosses Karawang Regency. It has been reported that the water in the Citarum river is of poor quality, making it unsuitable for drinking. This fact illustrates that the water in the Citarum river contains high pollutants. It should be noted that 18 sub-districts in Karawang Regency are crossed by the downstream segment of the Citarum River. Furthermore, it is shown that the high pollutant load of COD, BOD, phosphate and nitrate in the downstream section of the Citarum river. The high pollutant load found in the Citarum river
characteristics of infertile communities living in agricultural and industrial areas. The purpose of this study was to determine the characteristics of infertility in agricultural and industrial areas. The infertility characteristics include the results of sperm analysis, the etiology of the causes of infertility in females, and the diagnosis of infertility in the agricultural and industrial areas in Karawang Regency, West Java Province, Indonesia.

METHODS

This research is a retrospective study with descriptive analysis. This research is part of a research project on infertility characteristics in agricultural and industrial areas in Karawang Regency, West Java Province, Indonesia. Collection of medical record data used from January 1st to December 31st 2015. The individuals whose data were used in this study all live in Karawang Regency, West Java, Indonesia.

RESULTS

Based on the Table 1, showed infertility was most prevalent in males between 30 and 40 years (55.79%), followed by the age group below 30 years (36.84%) and above 40 years (7.37%). Meanwhile, in the female, infertility was most prevalent in the age group below 30 years (61.05%), followed by female aged 30-40 years (36.84%), and above 40 years (2.11%).

According to Table 2, the most common educational qualification possessed by male education is high school diploma (33.68%), followed by the academy (26.32%), junior high school (21.05%), and bachelor (18.95%) degrees. Similarly, the most prevalent educational qualification possessed by the female was high school diploma (36.84%), followed by junior high school (31.58%), academy (23.16%), and bachelor (8.42%) degrees.

Based on Table 3, infertility was discovered to be most prevalent in factory employees (56.84%), followed by entrepreneurs (29.47%), laborers (22.11%), and civil servant males (12.63%) in terms of occupation. Meanwhile, in the female, infertility cases were most prevalent in housewives (36.84%), followed by factory employees (23.16%), laborers (12.63%), and civil servants (12.63%).

Based on Table 6 shows that the most common infertility diagnosis was primary infertility male and female factor (45.26%), followed by primary infertility ex male factor (31.58%), primary infertility ex female factor (18.95%), and secondary infertility (4.21%).

According to Table 5, the etiology of infertility in females was discovered to be majorly due to polycystic ovary syndrome (PCOS), 26.32%, followed by endometriosis 21.05%, tubal factors 20.0%, myoma 16.84%, and ovulation 15.79%.

Based on Table 6 shows that oligoasthenotatozoospermia being the most prevalent sperm type (33.68%), followed by oligoteratozoospermia (23.16%), oligoasthenospermia (21.05%), teratospermia (7.37%), oligospermia (6.32%), normospermia (4.23%), and asthenospermia (4.23%).

DISCUSSION

This study showed that infertility is most prevalent in males between 30 and 40 years (55.79) and females below 30 years (61.05%). Ordinarily, these age groups ought to be rather reproductive. However, on the contrary, these are the groups with the most infertility problems. Meanwhile, the highest educational qualification possessed by the male and female is High School diploma (33.68% and 36.84%, respectively). That is a possible early indication of the factories’ harmful impact in work environments and around residences. It has been reported that demographic factors such as gender, education, income and geographic location influence the prevalence of infertility in fertile Chinese men and women. Besides, the general levels of education, knowledge, and socioeconomic development within the region are currently low. Consequently, many people...
are ignorant or forced to live near factories and to utilize polluted water sources. In terms of occupation, the males were mostly laborers (56.84%), while the female was mostly housewives (36.84%). The occupation of laborers is a possible cause of infertility, especially in exposure to heat and direct contact with heat sources, often encountered in the manufacture of the metal rim, tires, steel plates, zinc, machine operators, motorcycle body frames, forklifts, and other products. This exposure of male reproductive organs to heat is possibly associated with reduction in sperm quality. That can occur because high temperatures cause an increase in testicular metabolism so that sperm is damaged.  

Pollution has detrimental effects on health, not only by direct inhalation of pollutants but also through other means of exposure, including ingesting contaminated water or skin contact. One easy example is carbon monoxide as a pollutant from industrial activities. In humans, carbon monoxide poisoning affects the cardiovascular, neurological, and affective systems. The most common health effects are respiratory infections. However, pollutants affect all body systems, including reproduction. The exact pathophysiology of the pollutant effect on ovaries is not currently known. However, pollutants bind to hemoglobin during blood circulation and cause toxicity upon entering body organs. We already know that agricultural and industrial activities produce pollutants as a by-product. Therefore the negative effects of pollutants on the population must be avoided. Also, the government has long-established technical guidelines for industrial estates (Pedoman Teknis Kawasan Industri).  

Based on the diagnosis of infertility, this study showed that the main factor of male and female infertility has the biggest role compared with the other factors (Table 4). We already know that various hormones play a role in the reproductive process, including gonadotrophin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), estrogen, progesterone, testosterone, and inhibin. It has been proven that estrogen plays a role in the reproductive system of women and men. Apart from that, estrogen also plays a role in the neuroendocrine, skeletal, vascular and immune systems. Therefore, estrogen has implications for infertility and other diseases. Therefore, exogenous estrogenic compounds have the potential to interfere with the reproductive system. In this regard, the effects of diethylstilbestrol (DES) and methoxychlor (MXC) have been investigated on female rhesus monkeys’ peripubertal period. These studies’ results indicate that DES had a striking effect on adolescent maturation, and MXC also altered development during this period. The pattern of effects across agents and doses may be based on specifics of estrogenic action. On the other hand, it has also been proven that xenoestrogens is involved in the decrease in the number and quality of human sperm, consequently contributing to a decrease in fertility and decline in the proportion of male births. Xenoestrogens have also been shown to increase the occurrence of abnormalities in the male reproductive tract. Moreover, it has also been shown that xenoestrogens play a role in increasing spontaneous abortion.  

It has been stated that primary infertility is associated with protein that binds with sex hormones. In humans, some proteins bind with sex hormones in the circulatory system and the testes. The protein that binds with sex hormones in the circulating system is called sex hormone-binding globulin (SHBG). Proteins that bind to sex hormones in the testes are called androgen binding proteins (ABP). SHBG in the circulatory system has a function to bind sex steroid hormones and mediate the work of these hormones to target cells outside the testes, while ABP functions to mediate the action of sex steroid hormones in the testes. It is shown that the distribution of SHBG concentrations is broad-based on age and body mass index (BMI) values in primary infertile men. From these two variables, it turns out that the relationship between BMI and a decrease in SHBG levels is stronger than the relationship between age and increased levels of SHBG. The other study showed that the levels of SHBG, total testosterone, free testosterone and percent of free testosterone have a negative correlation with age, but the insulin and free testosterone index do not correlate with age. The decrease in SHBG levels per decade in healthy Indonesian men was 8.19%, while the decrease of total testosterone levels per decade in healthy Indonesian men was 9.8%. The results of previous studies show that low total testosterone levels can increase fasting blood glucose levels in adult men, but SHBG levels do not predict fasting blood glucose levels. Although it has been stated that SHBG levels are influenced by many factors, including genetic factors such as the genetic polymorphism of SHBG.  

Research has been carried out concerning primary infertility to reduce SHBG levels in postmenopausal women, namely by isoflavone supplementation. We recommend that this method be implemented in women of childbearing age to increase fertility. Also, women of childbearing age in industrial areas also need special attention to BMI, especially those less than 18.5 kg/m². We recommend that women of childbearing age in these areas have a normal BMI. We need to present this matter because our results show that women of reproductive age with a BMI <18.5 kg/m² and having a heterozygous variant SHBG genotype (W/W) is undernutrition. Moreover, it has also been shown that women of childbearing age with a BMI <18.5 kg/m² and having the heterozygous variant SHBG genotype (W/W) have lower protein, fat and carbohydrate intake. It has been stated that gene mutations cause abnormalities in protein metabolism in cells. Disorders of protein metabolism in cells cause various forms of organ abnormalities, resulting in congenital abnormalities and morphological variations. Therefore, it is necessary to improve nutrition for reproductive women in agricultural and industrial areas such as in Karawang Regency, West Java Province, Indonesia.  

Various natural ingredients can be used as a source of protein. Proteins that are sourced from natural materials can be developed to meet protein intake. Moreover, it has also been shown that proteins from natural ingredients contain several enzymes with the potential for therapy. All the above studies’ results that reveal the role of SHBG in both men and
women's reproductive systems clarify the relationship between SHBG and primary infertility. Apart from hormones and SHBG, which can affect primary infertility, it is necessary to discuss pollutants that affect populations in agricultural and industrial areas.

Based on the etiology of infertility in female subjects, this study indicates that PCOS ranks top, which is 26.32% of the total subjects. PCOS is potentially valuable indicators of cultural, environmental, and genetic factors that may contribute to excess risk in certain world regions. It has been proven that the prevalence of PCOS is determined by region and race/ethnicity. The results of a study in the US showed that the prevalence of PCOS in the southern region was 47.5%, in the central region at 23.0%, while in the western region it was 18.7% and in the northeast region 10.3%. Also, it has also been stated that genetic and environmental (lifestyle) factors are associated with the pathophysiology of PCOS after prenatal exposure to androgens. Moreover, environmental toxins, dietary diet, obesity, and geographical variations are associated with PCOS. Besides these pollutants, bisphenol A (BPA) is made by combining acetone and phenol. BPA is used in food packaging and in general as an industrial ingredient. BPA exposure to humans can be through inhalation, skin and digestive tract. BPA has weak estrogenic, anti-androgenic, and antithyroid activity, although it can accumulate in various human body tissues. It has been reported that BPA affects metabolism and the reproductive system in humans. It is more detailed than BPA decreases male and female fertility. In more detail, it shows the impact of 2,2-bis (4-hydroxyphenyl) propane=BPA) as a water and soil pollutant with PCOS incidence. The results of previous studies showed that the women with PCOS had higher blood levels of BPA than the control group. With the high percentage of primary infertility in this study, research on various pollutants in agricultural and industrial areas in Karawang Regency, West Java Province, Indonesia, should be conducted.

Oligoasthenoteratozoospermia in this study reached 33.68% of the population (N=95 subjects). The results of this study are different from study results in India. A study in India showed that 3.8% of 105 men with fertility problems experienced oligoasthenoteratozoospermia. We suspect that the high prevalence of oligoasthenoteratozoospermia in the group of infertile men in this study is related to environmental pollutants. It has been explained previously that high pollutant loads are found in the downstream part of the Citarum river, which crosses the Karawang Regency. Our statement follows the research results, which state a significant positive correlation between seminal total PCB level and the percentage of single-stranded DNA in sperm.

CONCLUSION

Primary infertility of male and female factors, polycystic ovary syndrome and oligoasthenoteratozoospermia dominate the population in agricultural and industrial areas in Karawang Regency, West Java Province, Indonesia. Therefore, it requires supervision and protection from the government, society, factory owners, and related health workers. This study is intended to overcome the impact of pollutants that threaten residents who live and work in agricultural and industrial areas in Karawang district, West Java Province, Indonesia. Of course, this is also applied in the other agricultural and industrial areas in Indonesia.

ACKNOWLEDGEMENTS

We express our deep gratitude to the Leaders and Staff of Mitra Bunda Amanda Hospital, Karawang, Karawang Regency, West Java Province, Indonesia, for facilitating data collection and data validation.
