INTRODUCTION

Entering old age will be followed by changes and decreases in all body systems; one of them is the cardiopulmonary system. Pulmonary changes in the elderly include decreased muscle mass and tone, leading to reduced lung expansion and decreased chest wall compliance due to osteoporosis and calcification of costal cartilage. Several morphological changes reduce the respiratory efficiency of the chest wall and diaphragm in the elderly. The cross-sectional area of the intercostal muscles begins to decrease after 50 years old and this reduction is more significant in the expiratory muscles. Maximum static inspiratory and expiratory pressure decreases with aging, reflecting a decrease in respiratory muscle strength.

A decrease in the respiratory system’s ability and the strength of the respiratory muscles will affect the ability of the thoracic cage to expand and contract during breathing, which is called thoracic expansion. The expansion of both the upper and lower thoracic will experience a decline when a person begins to enter the elderly. The measurement of thoracic expansion can be used as a measure to determine the function of respiration. Thorax expansion measurement was done quantitatively by using the midline. Measurements were made at the peak of inspiration and maximum expiration.

Increasing the expansion of the thorax cage will affect respiratory control, coughing ability, and lung vital capacity. The vital lung capacity is the maximum volume of air released by the lungs after maximum inspiration. Measurement of vital lung capacity can give important information about the strength of respiratory muscles. Based on those mentioned above, this study aims to evaluate a correlation between the mobility of the thorax cage and the vital lung capacity of the lungs in the elderly.

METHODS

This cross-sectional study was conducted from 5 up to 6 June 2020 in Sulangai Village, Badung Regency, Bali, Indonesia. The sample of this study was the elderly who were taken from the population in the village by using the purposive sampling technique. The sample criteria are male and female, amounting to 20 people with an age range of 60-75 years, and the sample does not have a history of comorbidities, especially on cardiorespiratory.
collection techniques are tests and measurements with the midline instrument to measure the expansion of the upper and lower thorax in units of centimeters (cm), the Spirometer brand of Riester to measure the lung’s vital capacity in a liter (L). The measurement of the upper thoracic expansion was carried out in a circle with a point in the third intercostal space on the midclavicular line, while the lower thoracic expansion was at the xiphoid process. Both measurements are taken at the peak of inspiration and maximum expiration. The respondents were asked for maximum inspiration, then maximum expiration and the value that can be achieved on the spirometer will be seen. The data analysis includes a univariate (age, gender, chest expansion, and lung vital capacity) and multiple correlation test with a significance value of $p < 0.05$. Data were analyzed using SPSS version 20 for windows.

**RESULTS**

Based on the results of descriptive analysis, the average age was 68.4±5.78 years, that each male and female were 10 people. In the upper thorax expansion data, the mean was 86.25±7.51 cm, while the lower thorax expansion data obtained a mean of 79.20±7.24 cm. In addition, it was also found that the male thorax expansion tended to be greater than the female (Figure 1). The mean vital lung capacity in the sample was 1.18 ± 4.17 L (Table 1).

Based on the results of multiple correlation analyses of the upper and lower thorax expansion with vital lung capacity in the elderly, the correlation coefficient was 0.784, followed by the r-square value (0.614) and the p-value (0.000) (Table 2).

The R-value is 0.784 shows the strong correlations between upper and lower thorax expansion with the vital lung capacity in the elderly. The simultaneous contribution of upper and lower thorax expansion toward the vital lung capacity was 61.4%, according to the r-square value (Table 2). The p-value of 0.000 ($p < 0.05$) shows a significant correlation between upper and lower thorax expansion with vital lung capacity in the elderly (Table 2).

**DISCUSSION**

The research data shows that the overall average expansion of the upper and lower thorax in the sample of male elderly is higher than female elderly. This is because a previous study conducted by Adedoyin RA et al., stated that men’s chest expansion was significantly higher than women’s chest expansion. This is likely due to differences in the structure of respiration anatomy between men and women. Based on the research data results, it shows that the entire sample has less value on the lung vital capacity. This value continues to decline in line with age and occurs in both male and female samples. The research was conducted by Abdullah S et al., found that lung function changes in line with age addition. A significant decrease in lung function occurs at the age of more than 60 years old. This is due to changes in the airway, possibly followed by weakness in the respiratory muscles.

Research by Lee J et al., shows that lung capacity will decrease with age addition. This is due to changes in the structure of the thorax and weakness of the respiratory muscles. These changes will cause a decrease in the expansion of the thorax. According to Park JJ et al., increasing the thorax cage’s mobility will affect respiratory control, coughing ability, and lung vital capacity.

This study shows a strong positive significant correlation between the mobility of the thorax cage (upper and lower thorax expansion) and the vital lung capacity. **Table 1.** Baseline characteristic of respondents

capacity in the elderly. The similar result was also found by a study of Amatya M and Pun DB where the measurement of lung function with a spirometer statistically has a strong correlation to thorax expansion. While the results of Putri IDAJ et al., showed that normal chest development increased thorax expansion, affecting muscle tone. Inspiration and expiration and can increase the amount of air in and out of the lungs, so that able to increase the volume and vital capacity of the lung.

The research was conducted by Reddy RS et al., showed that measurements of upper and lower thorax expansion have inter-rater and inter-rater reliability and reproducibility in healthy subjects, smokers, and COPD. Upper and lower thorax expansion correlate with pulmonary function parameters as measured by a spirometer. The same thing also supported by the research was conducted by Wahyudi TA et al., regarding breathing exercises in divers who state that the results after training can lead to an increase in VO2 max value, an increase in vital lung capacity, and an increase in thorax expansion. The highest VO2 max has the best thorax capacity expansion and VO2 max itself has a close correlation with the vital lung capacity, so indirectly, thorax expansion has an increasing or decreasing effect on the lung vital capacity.

Previous studies were also provided similar results where there was a correlation between the vital lung capacity with the mobility of the thorax. If the thorax expansion decreases, the vital lung capacity will also reduce, and so will the contrary. This is also closely related to the statement that the vital lung capacity is the maximum air total that can be exhaled strongly after maximum inspiration.

CONCLUSION

This study shows a strong positive significant correlation between the mobility of the upper and lower thorax cages with the vital lung capacity in the elderly. In the implementation of this research, the subject was still limited. In future research, it will be necessary to increase research subjects and cover a wider area.
